## ABSTRACT

**Objective:** To present the arthroscopic surgical technique and the evaluation of the results from this technique for treating elbow stiffness. **Methods:** Between April 2007 and January 2010, ten elbows of ten patients with elbow stiffness underwent arthroscopic treatment to release the range of motion. The minimum follow-up was 11 months, with an average of 27 months. All the patients were male and their average age was 32.8 years (ranging from 22 to 48 years). After the arthroscopic treatment, they were followed up

weekly in the first month and every three months thereafter. The clinical evaluation was made using the criteria of the University of California at Los Angeles (UCLA). **Results:** All the patients were satisfied with the results from the arthroscopic treatment. The average UCLA score was 33.8 points. **Conclusion:** Arthroscopic treatment for elbow stiffness is a minimally invasive surgical technique that was shown to be efficient for treating this complication.

## INTRODUCTION

Elbow stiffness may result from a variety of causes, such as acute or chronic trauma, spasticity, heterotopic ossification, coma, burns, free bodies, synovitis and osteophytes in the proximal ulna, among others<sup>(1-4)</sup>. It is observed in 3 to 6% of patients who suffer a supracondylar fracture and in 33 to 100% of patients who undergo surgical procedures to treat fractures of the proximal radial neck<sup>(5,6)</sup>.

However, if nonsurgical treatment is instituted early on, with physiotherapy and dynamic bracing, for example, this may result in improvement of the range of motion of the elbow<sup>(7,8)</sup>.

Equally, if conservative treatment fails, several surgical techniques are capable of releasing the elbow contractures<sup>(9-13)</sup>.

The American Academy of Orthopaedic Surgeons (AAOS) has defined the normal range of motion (ROM) of the elbow as flexion from 0° to 146°<sup>(14)</sup>. On the other hand, Morrey et al<sup>(15)</sup> demonstrated that 90% of all activities of daily living can be accomplished with ROM from 30° to 130°.

Thus, the indications for surgical treatment may relate to situations of elbow extension of less than 30°, painful end extension of less than 30° or elbow contractures of less than 30° of extension that impede certain functional demands<sup>(16)</sup>.

The purpose of the present study was to assess the results obtained from the arthroscopic surgical technique for treating elbow stiffness.

## METHODS

Between April 2007 and January 2010, ten elbows of ten patients underwent arthroscopic treatment for elbow stiffness and reassessment. The operations were carried out by the Shoulder and Elbow Surgery Group of Bahia, at the Traumatological and Orthopedic Accident Clinic (CATO) and at Hospital Moinhos de Vento, Porto Alegre, RS, and were evaluated after receiving approval from the institutions' ethics committees.

The length of follow-up ranged from 11 to 37 months, with a mean of 27 months. The patients' mean age was 32.8 years, ranging from 22 to 48 years of age. All the patients were male (Table 1).

**Table 1** – Data on patients.

Patient number	Sex	Age	UCLA	Postoperative follow-up (months)
1	Male	32 years	33	37
2	Male	28 years	34	34
3	Male	36 years	34	24
4	Male	48 years	35	24
5	Male	22 years	35	13
6	Male	25 years	31	30
7	Male	48 years	32	26
8	Male	24 years	34	18
9	Male	40 years	35	17
10	Male	25 years	35	14

UCLA = University of California at Los Angeles method for assessing postoperative results.

With regard to pronation /supination, all the patients maintained their functional ROM, and none of them presented any major limitation other than the compromised flexion-extension (mainly extension). The cause or origin of the elbow stiffness varied, with predominance of traumatic etiology, and the patients' preoperative ROM ranged from 30° to 60° (Table 2).

The patients were referred for physiotherapy procedures and were released for activities of daily living as soon as possible, which was around the second postoperative day, according to their pain threshold. Thus, the importance of early mobility was empha-

**Table 2** – Data on patients.

Patient number	Cause/Origin	ROM (extension) Before operation	ROM (extension) After operation	ROM gain
1	Degenerative	40°	15°	25°
2	Traumatic	40°	10°	30°
3	Osteochondromatosis	35°	0°	35°
4	Traumatic	30°	0°	30°
5	Traumatic	35°	0°	35°
6	Traumatic	60°	15°	45°
7	Rheumatic	40°	10°	30°
8	Traumatic	45°	10°	35°
9	Traumatic	55°	0°	55°
10	Traumatic	30°	0°	30°

sized. The patients were followed up every week for the first month after the arthroscopic procedure, and then every month for the first three months and every three months thereafter.

The method chosen for clinical assessments on the patients after the operation was based on the UCLA criteria (University of California at Los Angeles)<sup>(17)</sup>.

## SURGICAL TECHNIQUE

Surgery was performed in all cases with the patient positioned in lateral decubitus, under general anesthesia and plexus block (Figure 1). For all the patients, we used a pneumatic tourniquet applied to the "root" of the limb, and an infusion pump at an atmospheric pressure of 30 mmHg.

**Figure 1** – Positioning of the patient in lateral decubitus.

We started to access the joint through an anterolateral portal that was constructed 2 cm anteriorly and 2 cm distally to the lateral epicondyle (Figure 2). The joint capsule was distended using 15 ml of saline solution (Figure 3). After introducing the optical device through the anterolateral portal, we then inspected the anterior region of the joint. By using the “inside out” technique, with placement of a Steinmann wire from a cannula positioned laterally and brought to the exterior medially, we constructed an anteromedial portal safely, without the risk of compromising the ulnar nerve (Figures 4 and 5).

With these two portals established, the procedure of joint release could begin. The optical device was kept in the anterolateral portal and the instrumentation was done through the anteromedial portal (Figure 6). We used a soft-tissue resection blade (shaver), generally with a diameter of 5 mm, to remove the synovium from the anterior joint capsule of the stiff elbow. Whenever possible, we created a proximal access portal, 1 cm anteriorly and proximally to the

anterolateral portal, through which the assistant surgeon introduced a snout-like spacer, in an attempt to push away the anterior soft tissue from the joint capsule (Figure 7).

Upon opening the anterior joint capsule, we started to perform capsulectomy using a basket-like instrument that was slid distally to proximally and medially to laterally, as far as the level of the head of the radius.

At this moment, we inverted the working portals so that the radial nerve could be dissected and the anterior capsulectomy could be completed, through the anterolateral portal. The ROM of the elbow was then tested.

If it was observed that there was still some limitation of ROM, we began posterior capsulectomy through the posterocentral portal (directly into the olecranon fossa), the superior posterolateral portal (1 cm proximally and 1 cm laterally to the posterocentral portal) and the inferior posterolateral portal (1 cm distally and 1 cm laterally to the posterocentral portal (Figure 8).

**Figure 2** – Anterolateral portal.

**Figure 4** – Anteromedial portal.

**Figure 3** – Distention of the capsule using saline solution.

**Figure 5** – Introduction of trochanter, laterally to medially.

**Figure 6** – Introduction of medial cannula through trochanter.

**Figure 7** – Snout-like spacer for anterior soft tissue.

**Figure 8** – Construction of posterior portals.

After releasing the elbow stiffness, we left a 3.2 suction drain in two accesses (anterior and posterior; these were removed one day later). Compressive bandaging was applied across the region, and we stimulated early mobility of the operated elbow: as early as possible, i.e. around the second postoperative day.

## RESULTS

The mean postoperative follow-up was 27 months, ranging from four to 37 months (Table 1).

Through using the UCLA scale evaluation method<sup>(17)</sup>, we found good and excellent results in all the cases, with a mean of 33.8 points and range from 31 to 35 points (Table 1).

All the patients were satisfied with the results from the arthroscopic surgical treatment, and their elbows reached a very functional level of ROM.

The amount of gain of elbow joint ROM ranged from 25° to 55° (Table 2).

There were some complications during the immediate postoperative period, including a case of pain that was unusually strong pain for a minimally invasive procedure and a case of fistula due to accumulation of intra-articular fluid, which was soon resolved, after around two weeks, and did not compromise the final postoperative result.

## DISCUSSION

Various causes may lead to elbow stiffness, such as trauma, free bodies, synovitis or heterotopic ossification, among others<sup>(1-4)</sup>. The great majority of such patients with elbow stiffness acquire this condition through trauma. In our study, this was an absolute finding among our patients.

Different authors agree that if nonsurgical treatment is instituted early on, with physiotherapy and dynamic bracing, for example, it may result in improvement of elbow ROM<sup>(7,8)</sup>. However, in all cases that we have treated and managed using physiotherapy without surgery, the results achieved for these patients. Several surgical techniques are capable of releasing elbow contractures<sup>(9-13)</sup>. Among these, arthroscopic release has been shown to be a truly effective procedure. All the patients in our sample presented good or excellent results, which corroborates our initial affirmation. The arthroscopic technique made it possible to view and treat the associated intra-articular lesions and enabled an early return to activities<sup>(18)</sup>. Because this is a minimally invasive surgical procedure, with consequently less surgical aggression, patients are more quickly able to return to their activities of daily living.

In 1995, Kim et al<sup>(10)</sup> demonstrated gains in extension of 7° and flexion of 17° after arthroscopic

treatment of elbow stiffness. In our study, we achieved much greater gains in extension for our patients' elbows (mean gain of 35°), with a patient satisfaction rate as good as in the previous paper. However, our results were very similar to those of Aldridge et al<sup>(19)</sup>, who achieved a mean gain in extension of 37° for their patients' elbows.

Among the disadvantages and complications of arthroscopic procedures on the elbow, with any treatment aim, the risk of neurovascular lesions while constructing the portals is one of the most feared<sup>(19)</sup>. Seeking to minimize the risks of this procedure, we also made a point of following the guidance of Gallay et al<sup>(20)</sup>. These authors evaluated the intra-articular volumetric capacity of the elbow and suggested that for clinical purposes, capsule distention using around

15 ml of fluid was recommendable, with the aim of avoiding risks to the joint capsule and neurovascular structures. Fortunately, all the complications that appeared in our patients were temporary and did not leave any trail of sequelae.

## CONCLUSION

Arthroscopic treatment for elbow stiffness was shown to be a technique with low surgical aggression that was efficient in promoting pain relief, with correction of the deformity and recovery of the ROM over a short space of time.

This is a low-morbidity procedure that is easy to apply after mastering the technique. It constitutes an excellent resource for treating elbow stiffness.
